Parallel Computing

A parallel computer is a collection of processors usually of the same type, interconnected to allow coordination and exchange of data.

The processors are primarily used to jointly solve a given problem.

Distributed Systems

A set of possibly many different types of processors are distributed over a larger geographic area.

Processors do not work on a single problem.

Suppose a problem *P* has sequential complexity $T^*(n)$, i.e., there is no algorithm that solves *P* in time $o(T^*(n))$.

Definition 1

The speedup $S_p(n)$ of a parallel algorithm A that requires time $T_p(n)$ for solving P with p processors is defined as

$$S_p(n) = \frac{T^*(n)}{T_p(n)}$$

Clearly, $S_p(n) \le p$. Goal: obtain $S_p(n) \approx p$.

It is common to replace $T^*(n)$ by the time bound of the best **known** sequential algorithm for *P*!

3 Introduction

▲ 個 ト ▲ 臣 ト ▲ 臣 ト 15/295

Suppose a problem *P* has sequential complexity $T^*(n)$, i.e., there is no algorithm that solves *P* in time $o(T^*(n))$.

Definition 1

The speedup $S_p(n)$ of a parallel algorithm A that requires time $T_p(n)$ for solving P with p processors is defined as

$$S_p(n) = \frac{T^*(n)}{T_p(n)} \; .$$

Clearly, $S_p(n) \le p$. Goal: obtain $S_p(n) \approx p$.

It is common to replace $T^*(n)$ by the time bound of the best **known** sequential algorithm for *P*!

Suppose a problem *P* has sequential complexity $T^*(n)$, i.e., there is no algorithm that solves *P* in time $o(T^*(n))$.

Definition 1

The speedup $S_p(n)$ of a parallel algorithm A that requires time $T_p(n)$ for solving P with p processors is defined as

$$S_p(n) = \frac{T^*(n)}{T_p(n)} .$$

Clearly, $S_p(n) \le p$. Goal: obtain $S_p(n) \approx p$.

It is common to replace $T^*(n)$ by the time bound of the best **known** sequential algorithm for *P*!

Definition 1

The speedup $S_p(n)$ of a parallel algorithm A that requires time $T_p(n)$ for solving P with p processors is defined as

$$S_p(n) = \frac{T^*(n)}{T_p(n)}$$

Clearly, $S_p(n) \le p$. Goal: obtain $S_p(n) \approx p$.

It is common to replace $T^*(n)$ by the time bound of the best **known** sequential algorithm for P!

Definition 2

The efficiency of a parallel algorithm A that requires time $T_p(n)$ when using p processors on a problem of size n is

$$E_p(n) = \frac{T_1(n)}{pT_p(n)}$$

 $E_p(n) \approx 1$ indicates that the algorithm is running roughly p times faster with p processors than with one processor.

Note that $E_p(n) \leq \frac{T_1(n)}{pT_{\infty}(n)}$. Hence, the efficiency goes down rapidly if $p \geq T_1(n)/T_{\infty}(n)$.

Disadvantage: cost-measure does not relate to the optimum sequential algorithm.

Simplicity

A model should allow to easily analyze various performance measures (speed, communication, memory utilization etc.).

Results should be as hardware-independent as possible.

Implementability

Parallel algorithms developed in a model should be easily implementable on a parallel machine.

Theoretical analysis should carry over and give meaningful performance estimates.

A real satisfactory model does not exist!

Example: Addition

Here, vertices without incoming edges correspond to input data. The graph can be viewed as a data flow graph.

3 Introduction

The DAG itself is not a complete algorithm. A scheduling implements the algorithm on a parallel machine, by assigning a time-step t_v and a processor p_v to every node.

Definition 3

A scheduling of a DAG G = (V, E) on p processors is an assignment of pairs (t_v, p_v) to every internal node $v \in V$, s.t.,

- $p_{\psi} \in \{1, \dots, p\}; t_{\psi} \in \{1, \dots, T\}$
- $= t_u = t_v \Rightarrow p_u \neq p_v$
- $(u,v) \in E \Rightarrow t_v \ge t_u + 1$

The DAG itself is not a complete algorithm. A scheduling implements the algorithm on a parallel machine, by assigning a time-step t_v and a processor p_v to every node.

Definition 3

A scheduling of a DAG G = (V, E) on p processors is an assignment of pairs (t_v, p_v) to every internal node $v \in V$, s.t.,

- $p_{v} \in \{1, \dots, p\}; t_{v} \in \{1, \dots, T\}$
- $t_u = t_v \Rightarrow p_u \neq p_v$
- $(u, v) \in E \Rightarrow t_v \ge t_u + 1$

The DAG itself is not a complete algorithm. A scheduling implements the algorithm on a parallel machine, by assigning a time-step t_v and a processor p_v to every node.

Definition 3

A scheduling of a DAG G = (V, E) on p processors is an assignment of pairs (t_v, p_v) to every internal node $v \in V$, s.t.,

•
$$p_{v} \in \{1, \dots, p\}; t_{v} \in \{1, \dots, T\}$$

•
$$t_u = t_v \Rightarrow p_u \neq p_v$$

 $\bullet (u, v) \in E \Rightarrow t_v \ge t_u + 1$

The DAG itself is not a complete algorithm. A scheduling implements the algorithm on a parallel machine, by assigning a time-step t_v and a processor p_v to every node.

Definition 3

Every processor executes the same program.

However, the program has access to two special variables:

- p: total number of processors
- $id \in \{1, \dots, p\}$: the id of the current processor

Every processor executes the same program.

However, the program has access to two special variables:

- p: total number of processors
- $id \in \{1, \dots, p\}$: the id of the current processor

```
Algorithm 1 copy1: if id = 1 then round \leftarrow 12: while round \leq p and id = round do3: x[id + 1] \leftarrow x[id]4: round \leftarrow round + 1
```

Every processor executes the same program.

However, the program has access to two special variables:

- p: total number of processors
- $id \in \{1, \dots, p\}$: the id of the current processor

```
Algorithm 1 copy1: if id = 1 then round \leftarrow 12: while round \le p and id = round do3: x[id+1] \leftarrow x[id]4: round \leftarrow round + 1
```

Every processor executes the same program.

However, the program has access to two special variables:

- p: total number of processors
- $id \in \{1, \dots, p\}$: the id of the current processor

Algorithm 1 copy	
1:	if $id = 1$ then $round \leftarrow 1$
2:	while $round \le p$ and $id = round$ do
3:	$x[id+1] \leftarrow x[id]$
4:	$round \leftarrow round + 1$

 processors can effectively execute different code because of branching according to *id*

however, not arbitrarily; still uniform model of computation

Often it is easier to explicitly define which parts of a program are executed in parallel:

- processors can effectively execute different code because of branching according to *id*
- however, not arbitrarily; still uniform model of computation

Often it is easier to explicitly define which parts of a program are executed in parallel:

PRAM Model

- processors can effectively execute different code because of branching according to *id*
- however, not arbitrarily; still uniform model of computation

Often it is easier to explicitly define which parts of a program are executed in parallel:

```
Algorithm 2 sum
1: // computes sum of x[1] \dots x[p]
2: // red part is executed only by processor 1
3: \gamma \leftarrow 1
4: while 2^{\gamma} \leq p do
5: for id mod 2^r = 1 pardo
6: // only executed by processors whose id matches
7:
             x[id] = x[id] + x[id + 2^{r-1}]
   \gamma \leftarrow \gamma + 1
 8:
 9: return x[1]
```

Simultaneous Access to Shared Memory:

- EREW PRAM: simultaneous access is not allowed
- CREW PRAM:

concurrent read accesses to the same location are allowed; write accesses have to be exclusive

CRCW PRAM:

concurrent read and write accesses allowed

- common CRCW PRAM
- all processors writing to x[i] must write same value
- arbitrary CRCW PRAM
 - values may be different; an arbitrary processor succeeds priority CRCW PRAM
 - values may be different; processor with smallest id succeeds

5: x[id] = x[id] + x[id + 2^{r-1}]

6: r \leftarrow r + 1

7: return x[1]
```

The above is an EREW PRAM algorithm.

On a CREW PRAM we could replace Line 4 by for $1 \le id \le p$ pardo

Algorithm 3 sum

```
1: // computes sum of x[1]...x[p]

2: r \leftarrow 1

3: while 2^r \le p do

4: for id \mod 2^r = 1 pardo

5: x[id] = x[id] + x[id + 2^{r-1}]

6: r \leftarrow r + 1

7: return x[1]
```

The above is an EREW PRAM algorithm.

On a CREW PRAM we could replace Line 4 by for $1 \le id \le p$ pardo

- similar to a RAM we either need to restrict the size of values that can be stored in registers, or we need to have a non-uniform cost model for doing a register manipulation (cost for manipulating x[i] is proportional to the bit-length of the largest number that is ever being stored in x[i])
 - in this lecture: uniform cost model but we are not exploiting the model
- global shared memory is very unrealistic in practise as uniform access to all memory locations does not exist
- global synchronziation is very unrealistic; in real parallel machines a global synchronization is very costly
- model is good for understanding basic parallel mechanisms/techniques but not for algorithm development
- model is good for lower bounds

Computing the sum on a *d*-dimensional hypercube. Note that $x[0] \dots x[2^d - 1]$ are stored at the individual nodes.

```
Algorithm 4 sum
1: // computes sum of x[0] \dots x[2^d - 1]
2: r \leftarrow 1
3: while 2^r \le 2^d \text{ do } // p = 2^d
   if id mod 2^r = 0 then
4:
              temp \leftarrow receive(id + 2<sup>r-1</sup>)
5:
             x[id] = x[id] + temp
6:
7: if id mod 2^r = 2^{r-1} then
8:
             send(x[id], id -2^{r-1})
9: r \leftarrow r + 1
10: if id = 0 then return x[id]
```

Remarks

- One has to ensure that at any point in time there is at most one active communication along a link
- There also exist synchronized versions of the model, where in every round each link can be used once for communication
- In particular the asynchronous model is quite realistic
- Difficult to develop and analyze algorithms as a lot of low level communication has to be dealt with
- Results only hold for one specific topology and cannot be generalized easily

3 Introduction

Suppose that we can solve an instance of a problem with size n with P(n) processors and time T(n).

We call $C(n) = T(n) \cdot P(n)$ the time-processor product or the cost of the algorithm.

The following statements are equivalent

- P(n) processors and time $\mathcal{O}(T(n))$
- $\mathcal{O}(\mathcal{C}(n))$ cost and time $\mathcal{O}(T(n))$
- $\mathcal{O}(C(n)/p)$ time for any number $p \le P(n)$ processors
- O(C(n)/p + T(n)) for any number p of processors

Suppose that we can solve an instance of a problem with size n with P(n) processors and time T(n).

We call $C(n) = T(n) \cdot P(n)$ the time-processor product or the cost of the algorithm.

The following statements are equivalent

- P(n) processors and time $\mathcal{O}(T(n))$
- $\mathcal{O}(\mathcal{C}(n))$ cost and time $\mathcal{O}(T(n))$
- $\mathcal{O}(C(n)/p)$ time for any number $p \le P(n)$ processors
- $\mathcal{O}(C(n)/p + T(n))$ for any number p of processors

Suppose we have a PRAM algorithm that takes time T(n) and work W(n), where work is the total number of operations.

We can nearly always obtain a PRAM algorithm that uses time at most

W(n)/p] + T(n)

parallel steps on *p* processors.

Idea:

- $W_i(n)$ denotes operations in parallel step $i, 1 \leq i \leq T(n)$
- simulate each step in $[W_i(n)/p]$ parallel steps
- then we have

 $\sum_{i} |W_i(n)/p| \le \sum_{i} (|W_i(n)/p| + 3) \le |W_i(n)/p| + 3(n).$

Suppose we have a PRAM algorithm that takes time T(n) and work W(n), where work is the total number of operations.

We can nearly always obtain a PRAM algorithm that uses time at most

 $W(n)/p \rfloor + T(n)$

parallel steps on *p* processors.

Idea:

- $\mathcal{W}_i(n)$ denotes operations in parallel step $i, 1 \leq i \leq T(n)$
- simulate each step in $[W_i(n)/p]$ parallel steps
- then we have

 $\sum_{i} |W_i(n)/p| \le \sum_{i} (|W_i(n)/p| + 1) \le |W_i(n)/p| + 2(n).$

Suppose we have a PRAM algorithm that takes time T(n) and work W(n), where work is the total number of operations.

We can nearly always obtain a PRAM algorithm that uses time at most

 $\lfloor W(n)/p \rfloor + T(n)$

parallel steps on p processors.

Idea:

- $= W_i(n)$ denotes operations in parallel step $i, 1 \le i \le T(n)$ $= \text{simulate each step in } |W_i(n)/p|$ parallel steps
- then we have

 $\sum_{i} |W_i(n)/p| \le \sum_{i} (|W_i(n)/p| + 3) \le |W_i(n)/p| + 3(n)$

Suppose we have a PRAM algorithm that takes time T(n) and work W(n), where work is the total number of operations.

We can nearly always obtain a PRAM algorithm that uses time at most

$$W(n)/p \rfloor + T(n)$$

parallel steps on p processors.

Idea:

- ▶ $W_i(n)$ denotes operations in parallel step i, $1 \le i \le T(n)$
- simulate each step in $[W_i(n)/p]$ parallel steps
- then we have

$$\sum_{i} \left[W_{i}(n)/p \right] \leq \sum_{i} \left(\left\lfloor W_{i}(n)/p \right\rfloor + 1 \right) \leq \left\lfloor W(n)/p \right\rfloor + T(n)$$

Suppose we have a PRAM algorithm that takes time T(n) and work W(n), where work is the total number of operations.

We can nearly always obtain a PRAM algorithm that uses time at most

$$W(n)/p \rfloor + T(n)$$

parallel steps on p processors.

Idea:

- ▶ $W_i(n)$ denotes operations in parallel step *i*, $1 \le i \le T(n)$
- simulate each step in $[W_i(n)/p]$ parallel steps
- then we have

 $\sum_{i} \lceil W_{i}(n)/p \rceil \leq \sum_{i} \left(\lfloor W_{i}(n)/p \rfloor + 1 \right) \leq \lfloor W(n)/p \rfloor + T(n)$

Suppose we have a PRAM algorithm that takes time T(n) and work W(n), where work is the total number of operations.

We can nearly always obtain a PRAM algorithm that uses time at most

$$W(n)/p \rfloor + T(n)$$

parallel steps on p processors.

Idea:

- ▶ $W_i(n)$ denotes operations in parallel step *i*, $1 \le i \le T(n)$
- simulate each step in $[W_i(n)/p]$ parallel steps
- then we have

$$\sum_{i} \lceil W_{i}(n)/p \rceil \leq \sum_{i} \left(\lfloor W_{i}(n)/p \rfloor + 1 \right) \leq \lfloor W(n)/p \rfloor + T(n)$$

Why nearly always?

We need to assign processors to operations.

- every processor p_{f} needs to know whether it should be active
- in case it is active it needs to know which operations to perform

Why nearly always?

We need to assign processors to operations.

- every processor p₁ needs to know whether it should be active
- in case it is active it needs to know which operations to perform

Why nearly always?

We need to assign processors to operations.

- every processor p_i needs to know whether it should be active
- in case it is active it needs to know which operations to perform

Why nearly always?

We need to assign processors to operations.

- every processor p_i needs to know whether it should be active
- in case it is active it needs to know which operations to perform

Why nearly always?

We need to assign processors to operations.

for $p = \mathcal{O}(T^*(n)/T(n)).$

This means by improving the time T(n), (while using same work) we improve the range of p, for which we obtain optimal speedup.

We call an algorithm worktime (WT) optimal if T(n) cannot be asymptotically improved by any work optimal algorithm.

This means by improving the time T(n), (while using same work) we improve the range of p, for which we obtain optimal speedup.

We call an algorithm worktime (WT) optimal if T(n) cannot be asymptotically improved by any work optimal algorithm.

Algorithm for computing the sum has work W(n) = O(n). optimal

 $T(n) = O(\log n)$. Hence, we achieve an optimal speedup for $p = O(n/\log n)$.

One can show that any CREW PRAM requires $\Omega(\log n)$ time to compute the sum.

Algorithm for computing the sum has work W(n) = O(n). optimal

 $T(n) = O(\log n)$. Hence, we achieve an optimal speedup for $p = O(n/\log n)$.

Communication Cost

When we differentiate between local and global memory we can analyze communication cost.

We define the communication cost of a PRAM algorithm as the worst-case traffic between the local memory of a processor and the global shared memory.

Communication Cost

Split matrix into blocks of size $n^{2/3} \times n^{2/3}$.

Note that $C_{i,j} = \sum_{\ell} A_{i,\ell} B_{\ell,j}$.

Now we have the same problem as before but $n' = n^{1/3}$ and a single multiplication costs time $\mathcal{O}((n^{2/3})^3) = \mathcal{O}(n^2)$. An addition costs $n^{4/3}$.

Now we have the same problem as before but $n' = n^{1/3}$ and a single multiplication costs time $\mathcal{O}((n^{2/3})^3) = \mathcal{O}(n^2)$. An addition costs $n^{4/3}$.

The communication cost is only $\mathcal{O}(n^{4/3}\log n')$ as a processor in the original problem touches at most $\log n$ entries of the matrix.

Each entry has size $\mathcal{O}(n^{4/3})$.

The algorithm exhibits less parallelism but still has optimum work/runtime for just n processors.

much, much better in practise

The communication cost is only $\mathcal{O}(n^{4/3}\log n')$ as a processor in the original problem touches at most $\log n$ entries of the matrix.
